ABSTRACT

Two water-quality synoptic studies were made on the Colorado River in the Grand Canyon, Arizona. Field measurements and the collection of water samples for laboratory analysis were made at 10 mainstem and 6 tributary sites every 6 hours for a 48-hour period on November 5-6, 1990, and again on June 18-20, 1991. Field measurements included discharge, alkalinity, water temperature, light penetration, pH, specific conductance, and dissolved oxygen. Water samples were collected for the laboratory analysis of major and minor ions (calcium, magnesium, sodium, potassium, strontium, chloride, sulfate, silica as SiO_2), trace elements (aluminum, arsenic, boron, barium, beryllium, cadmium, cobalt, chromium, copper, iron, lead, lithium, manganese, molybdenum, nickel, selenium, thallium, uranium, vanadium and zinc), and nutrients (phosphate, nitrate, ammonium, nitrite, total dissolved nitrogen, total dissolved phosphorus and dissolved organic carbon). Biological measurements included drift (benthic invertebrates and detrital material), and benthic invertebrates from the river bottom.

INTRODUCTION

Studies concerned with large river systems, especially large impounded systems, have been limited (Petts, 1984; Ward and Stanford, 1979). Thus, there is an often meager understanding of physical, chemical, and biological water-quality constituents for any given downstream reach of the system that is affected by specific dam operations. The Colorado River is no exception. Originating in central Colorado, with its main tributary, the Green River, it flows through seven states and 2,250 river kilometers to the Gulf of Mexico. On its way to the sea, it drains a basin of about 647,500 square kilometers. Most of this drained area is in an arid climate where the annual precipitation is less than 25 centimeters (cm). Thus, the water of the Colorado River is extremely valuable from an agricultural and an urban standpoint. This high value of water has resulted in the construction of 13 storage reservoirs on the Colorado River and its tributaries. Lake Mead, perhaps the best known reservoir, was formed in 1936 when Hoover Dam was closed. Lake Powell, the most recent, was formed in 1963 when Glen Canyon Dam was closed.

Between Glen Canyon Dam and Lake Mead is the Grand Canyon of the Colorado River, which encompasses Grand Canyon National Park. There, the river flows through its bedrock channel between vertical canyon walls and over a number of rapids. The riverbed elevation drops about 210 meters within the 632 river kilometers between Lees Ferry, Arizona, and the mouth of Diamond Creek. Prior to 1960, before the closing of Glen Canyon Dam, fewer than 1,000 people had taken river trips through the Grand Canyon. Up to 1991, more than 25,000 people make the journey annually in rafts and boats. This use of the river has resulted in careful control of boaters and other users by the National Park Service. It also resulted in a need for camping sites along the river and an urgent need to evaluate human impact, including that of altering the quality of the river water.

In addition to human use of the river in the Grand Canyon is the operation of Glen Canyon Dam. The dam was constructed for flood control, power generation, and water storage to meet demands of the lower basin states and Mexico. Much controversy related to the dam is concerned with long daily fluctuations in water release for hydroelectric power generation. For example, within a 24-hour period, discharge from the dam commonly may range from 140 to 850 cubic meters per second (m^3/s). This flow variation causes erosion of the riverbank and sediment deposits used for camping and makes river rafting difficult. As a result, for more than a decade there has been public concern about the effects of Glen Canyon Dam on the Colorado River in the Grand Canyon. The dam and reservoir also have decreased sediment transport to the downriver area, which resulted in increased light penetration through the water. Water from Lake Powell is removed for electric power generation from penstocks located in the upper part of the hypolimnion (elevation 322 m). This water has a temperature of about 8 degrees Celsius (°C) throughout the year. Pre-dam water temperatures ranged from about 0 to 26 °C (Ferrari, 1986).

Physical alterations in the river channel are not the only concern. Several fish native to the river are now on the U.S. Fish and Wildlife Service Endangered Species List, and increased light has permitted profuse production of the algae organism, *Cladophera glomerata*, especially in the Lees Ferry area. The *Cladophera* production has resulted in organic loading to the river. There also is evidence that nitrogen and phosphorus concentrations in the river have decreased since the filling of Lake Powell (Gloss and others, 1980). These chemical and biological water-quality concerns have been known since dam closure and have been the subject of past studies.

Mindful of public concern about discharge regulation from Glen Canyon Dam, the Congress directed the U.S. Bureau of Reclamation (USBR) to undertake studies of the river and its channels. The first Glen Canyon study began in 1982 and concluded in 1987. It was known as the Glen Canyon Environmental Study I (GCES-I). The study resulted in a number of scientific papers and a study summary (U.S. Department of the Interior, 1988). A review of GCES-I was provided by the National Academy of Science (Marzolf, 1987). In 1988 the Congress extended the GCES-I study (renamed GCES-II) to include a wider array of topics and to address specific studies that were inconclusive during the GCES-I study. Moreover, during the period of the GCES-II studies, the Congress ordered the Secretary of the Interior to propose and conduct adjusted flows, called interim flows, and to evaluate the consequences of these flows on the Grand Canyon environment. The interim flows were begun in August 1991.

During the winter of 1989-90, the U.S. Geological Survey (USGS) prepared a proposal for scientific investigations of the Colorado River. The USGS proposal included a number of studies to be conducted in the Grand Canyon and on Lake Powell near the dam. Among the water-quality work proposed was a study to determine the chemical and biological resources and characteristics of the river between Glen Canyon Dam and Lake Mead.

Past water-quality work, including that accomplished during GCES-I, provided some insight about the chemical and biological resources of the river in the Grand Canyon, but was inconclusive regarding river-reach understanding. As a result, synoptic studies were designed by USGS scientists to obtain selected chemical and biological information along the Grand Canyon corridor of the river including the major tributaries. The goal of the synoptic studies was to obtain a study-length (Lake Powell forebay to Lake Mead and major tributaries) understanding of selected chemical and biological constituents so process-oriented studies could be designed in the future. In addition, sampling was organized on a temporal basis so interpretive information could be obtained to develop a better understanding of the effect of variable discharge (daily, cyclic water releases from Glen Canyon Dam) and diel variation. The design of the studies was to make field measurements and collect samples every 6 hours for 48 hours. In the original plan, synoptic studies were to be conducted during low light, low tributary flow (November); high light, low tributary flow (June) and high light, high tributary flow (August). Synoptic studies were conducted on November 5-6, 1990, and June 18-20, 1991. A third synoptic study scheduled for August 1991 was canceled for lack of funding.

The authors of this report wish to thank the volunteers who assisted us on the river during the November 1990 and June 1991 synoptic studies. We especially wish to pay tribute to the team leaders for their diligence in making field measurements, collecting water samples, and caring for their people while the synoptic studies were underway. . We wish to thank Charles Patton, USGS, for assisting in performing nutrient determinations. We are saddened by the untimely passing of R.C. Averett during the preparation of this report. His insight and leadership was a tremendous contribution to this study.

METHODS

A total of ten mainstem river sites, six tributary sites, and one site in the forebay of Lake Powell, were selected for sampling during each synoptic study (fig. 1). To minimize sampling variance, the river sites were sampled immediately upstream from the tributary mouth to ensure the sampling of a thoroughly mixed reach and the tributary site sampled near its mouth (table 1). During the November 1990 synoptic study, the collection of water samples and field measurements began at 0600 hours on November 5 and ended at 2400 hours on November 6. In June 1991, the collection of water samples and field measurements began at 1200 hours on June 18 and ended at 0600 hours on June 20. During each study, water samples were collected and field measurements were made eight times at 6-hour intervals Field measurements, sample collection, and the references for the technique used for analysis are shown in table 2. All water samples for chemical analysis were collected using the discharge-weighted depth- and width-integrated equal discharge increment (EDI) method (Edwards and Glysson, 1988). At cableways and non-wadable tributary sites, boats that had a boom and winch assembly were used, and samples were collected

with a modified US D-77 sampler (Edwards and Glysson, 1988). At wadable tributary sites, a US DH-81 (hand held) sampler was used. The US D-77 sampler has a capacity of 2 L. A Teflon bag of that volume was placed in the sampler bottle to avoid metallic contamination. In addition, the sampler was coated with an epoxy paint. All sampling equipment was handled with Teflon gloves to avoid contamination. At each vertical in the river, 1-1.5 L of water were collected. At the boat-sampled mainstem sites, sampling verticals were located at predetermined flow centroids that had equally spaced areas. Sample collection at cableways was made at five centroids of flow that were predetermined for given stage/discharge relations. At wading stations, the five discharge centroids were determined from discharge measurements made at the time of sampling. After a sample was collected using the US D-77 or US DH-81 sampler, it was transferred to a graduated cylinder by passing the sample through a 63 micrometer (μm) mesh nylon screen to remove sand-sized suspended matter, and the volume was recorded. The water then was transferred into a Teflon-coated stainless steel churn splitter (U.S. Geological Survey, 1976) for compositing. When all five centroids of flow were sampled, the churn contained about 7.5 L of sample water. The churn with the contained water then was removed to a processing site (often within a tent) and aliquots were subsampled as the churn paddle was in motion, ensuring a mixed sample. Water for trace-element analysis (table 2) was filtered through a 0.4-μm Nuclepore filter housed in an all-Teflon vacuum sample holder using ultraclean techniques. Samples for nitrogen, phosphorus, and dissolved organic carbon were filtered through a 0.45-μm silver-membrane filter. Specific sample preparation protocol and field measurement procedures are described in Taylor, Averett, and Garbarino (see Appendix).

Table 1.--Sampling site names and river kilometers for Colorado River synoptic studies

[Note: Lees Ferry is river kilometer 0.0]

Sampling site	River kilometer	Site No. for fig. 1
Lake Powell Forebay	-25.5	1
Colorado River below Glen Canyon Dam	-20.0	2
Colorado River at Lees Ferry	0.0	3
Paria River near mouth	0.7	4
Colorado River above Little Colorado River	98.3	5
Little Colorado River near mouth	98.5	6
Colorado River at Grand Canyon	141.0	7
Bright Angel Creek near mouth	141.5	8
Colorado River above Kanab Creek	230.5	9
Kanab Creek near mouth	230.7	10
Colorado River above Havasu Creek (November 1990 only)	252.1	11
Havasu Creek near mouth	252.3	12
Colorado River at National Canyon	268.1	13
Colorado River above Diamond Creek	363.1	14
Diamond Creek near mouth	363.3	15
Colorado River near Travertine Cleft (June 1991 only)	428.8	16
Colorado River near Columbine Falls (November 1990 only)	439.2	17

Field

Field measurements included water temperature measured with a calibrated hand-held alcohol thermometer. Temperature measurements were made every 6 hours when water samples were collected, but also at more frequent periods when time permitted. Water temperature was measured near the river or tributary surface where each depth-integrated water sample was collected. Temperature was recorded to the nearest 0.5 °C, after a 3-minute thermometer-equilibration period. Water for the measurement of pH and specific conductance was taken at the surface (grab) from the stream cross-section, and the pH was determined immediately. The pH was measured using an Orion Model SA 250 digital meter that was calibrated using buffers of pH 4.01, 7.0, and 10.00. Specific conductance was measured using an Amber Science Model 604 meter with a 515 conductivity cell. Specific conductance was measured immediately after sample collection. Dissolved oxygen (DO) was measured in the river and tributaries using a Yellow Springs Meter Model 54. The DO was reported to the nearest 0.1 milligram per liter (mg/L). At boat sampling and measuring sites and in tributaries where wading was possible, discharge was measured directly using a Price current meter. Light was measured during daytime hours using a Secchi disk (black and white quadrants) 30 centimeters (cm) in diameter. At cableways, discharge was determined from stage readings and rating curves, because all cableways have historic stage/discharge records.

Biological samples consisted of drift (benthic invertebrates and detrital material), and benthic invertebrates from the river and tributary bottom. During the synoptic studies, drift was collected at each site using a net having a 250-μm mesh opening, a 10-cm orifice diameter, and measuring 90-cm in length. Two nets were set in parallel just below the water surface and held in place by steel rods driven into the stream bottom. The nets were set at the beginning of each 6-hour synoptic study period and remained in the stream for 1-hour. Because of rapidly fluctuating water levels, it often was necessary to adjust the depth of the net orifice during the hour of collection. Water velocity was measured in front of each net to facilitate calculation of the amount of water that passed through the net during the hour of collection. After collection, the contents of each net were composited into jars and preserved with a 50 percent mixture of water and ethanol. At selected sites a drift net having a mesh size of 250-μm, an orifice diameter of 0.5-m, and a length of 1.6-m was towed behind a boat in the river center for 15 minutes. While in tow, the top of the net orifice was just below the water surface.

Wide fluctuations in water levels in the Colorado River downstream from Glen Canyon Dam result in streamside areas that are wet for only a short period of each day, and thus, do not support benthic invertebrates. Therefore, sampling for benthic invertebrates was conducted on the stream bottom only during the lowest flow that occurred during the 48-hour synoptic study period. A kick net having a mesh opening of 0.5-mm and measuring 1.1 x 1.0-m was used for collection (Britton and Greeson, 1987, p. 152). A stream bottom area of 1-m^2 was disturbed and the material was washed into the net. In addition, one square foot Surber samplers were used in slow moving water for the collection of bottom invertebrates. The invertebrates collected in the net were removed onsite and preserved in a 50 percent mixture of ethanol and water.

In the laboratory, benthic invertebrates were separated from detrital material and identified to genus and, whenever possible, to species at the University of Pittsburgh Pymatuning Laboratory of Ecology. Keys used for identification of the invertebrates were primarily from Merritt and Cummins (1984). The ash-free weight of the detrital material then was determined by using the technique described in Britton and Greeson (1987, p. 129-130).

Laboratory

Several laboratory instrumental methods were used for the analysis of samples collected during the synoptic studies. Techniques were selected based on their optimal use for specific measurement criteria, primarily accuracy, precision, sensitivity, and selectivity. These techniques have been developed over a period of several years for the specific application to environmental water analysis.

Alkalinity was determined using an automated Gran titration method (Kramer, 1982). Titrations were performed on a Radiometer auto-titrator using the supernatant portions of the sample after letting the sample settle for at least 24 hours and titrated with a 0.1 N standard sulfuric acid solution. Major cations were determined using inductively coupled plasma-atomic emission spectrometric (ICP-AES) analysis. Specific details of the method and techniques are described in Garbarino and Taylor (1979). The elements calcium, iron, magnesium, silica (as SiO_2), sodium, and strontium were determined simultaneously on a sample aliquot that had been filtered (0.4-μm) and acidified (HNO_3) in the field, using ultraclean procedures. Potassium was determined on the same aliquot by an air/acetylene flame atomic absorption spectrometric technique (Fishman and Friedman, 1985).

Selected trace elements including: aluminum, antimony, arsenic, boron, barium, beryllium, cadmium, cobalt, chromium, copper, lithium, manganese, molybdenum, nickel, lead, rubidium, selenium, silver, thallium, uranium, vanadium, and zinc were determined using state-of-the-art, inductively coupled plasma-mass spectrometric techniques described by Taylor (1989); Taylor and others (1990), Taylor and Garbarino, (1992),and Garbarino and Taylor (1993). These elements also were determined simultaneously on a single sample aliquot that was filtered in the field (0.4 μm) and acidified (HNO_3.

Nutrient determinations included dissolved ammonium ion, dissolved nitrate, dissolved nitrite, and dissolved orthophosphate. Ammonium, nitrate, nitrite, and phosphate were determined using the salicylate-hypochlorite absorption spectrophotometric procedure; sulfanilamide/N-1-napthylethylenediamine dihydrochloride with Cd reduction absorption spectrophotometric procedure; sulfanilamide/N-1-napthylethylenediamine dihydrochloride absorption spectrophotometric procedure; and phosphomolybdate absorption spectrophotometric procedure, respectively (Fishman and Friedman, 1985, and Antweiler and others, 1993).

RESULTS

Water temperature, specific conductance and DO at specific positions in the river cross section are listed for the November 1990 study in table 3 and for the June 1991 study in table 4.

Nutrient data for the November 1990 and June 1991 synoptics are listed in tables 7 and 8, respectively. The nutrient determinations are all made on dissolved constituents (that is, all samples filtered through a 0.45-μm silver membrane filter) and include the following specific determinations reported in mg/L as either nitrogen or phosphorus: ammonium (NH_4), nitrite ion (NO_2), nitrate ion (NO_3), total dissolved nitrogen, orthophosphate ion (PO_4), and total dissolved phosphorus.

pH, alkalinity, and dissolved organic carbon determinations are listed in table 5 for the November 1990 synoptic study and in table 6 for the June 1991 synoptic study. Major constituents are tabulated in table 9 for the November 1990 synoptic study and table 10 for the June 1991 synoptic study. These tables include calcium (Ca), magnesium (Mg), potassium (K), sodium (Na), sulfate (SO_4), chloride (Cl) and silica (SiO_2) and are reported in milligrams per liter.

Trace constituents are listed in tables 11 and 12 for the same respective synoptics and include: aluminum, arsenic, boron, barium, beryllium, cadmium, cobalt, chromium, copper, iron, lead, lithium, manganese, molybdenum, nickel, thallium, uranium, vanadium, and zinc. All concentrations are reported in micrograms per liter (μg/L) except iron which is reported in milligrams per liter.

Results of the taxonomic, functional groupings, numbers, and biomass of benthic invertebrates from drift samples are listed in table 13 for the November 1990 sampling period, and in table 16 for the June 1991 sampling

period. Similar information on invertebrates collected from kick nets is contained in table 14 for the November 1990 synoptic study and in table 17 for the June 1991 synoptic study. Similarly, data obtained from one square foot Surber nets are listed in table 15 for the November 1990 synoptic study and in table 18 for the June 1991 synoptic study. Detrital biomass collected with 10-cm diameter nets are reported in tables 19 and 20, for the respective synoptic studies. Results of similar detrital biomass determinations collected using 0.5-m diameter nets are listed in table 21 for the synoptic studies.

Tabulations of water discharge in cubic meters per second (m^3/s) during the synoptic sampling periods are listed in table 22 for November 1990 and table 23 for June 1991. Hydrographs for this period are plotted in figure 2 for the November 1990 synoptic study and in figure 3 for the June 1991 synoptic study. Suspended sediment concentrations are tabulated in table 24 for the November 1990 synoptic study and in table 25 for the June 1991 synoptic study.

APPENDIX

WATER QUALITY

SYNOPTIC EXPERIMENT FIELD GUIDE

U.S, Geological Survey

Water Resources Division

Colorado River Water-Quality Study

1991

Prepared by

H.E. Taylor, R.C. Averett and J.R. Garbarino

INTRODUCTION

In order to understand the water-quality of the river, the following measurements and water sample collection will be made as a part of the synoptic studies. During each synoptic period field measurements and water-sample collection will occur every 6 hours over a 48-hour period.

FIELD MEASUREMENTS

TEMPERATURE--Temperature will be measured each time samples are collected at each of the respective sampling locations. The general rule of thumb is "you never have too much temperature data"; therefore, whenever possible measure both the water temperature and ambient air temperature and record date, time, sampling site and measurement location on the provided form. All temperatures should be measured at the surface with a calibrated alcohol thermometer to the nearest 0.5 C. (NO mercury thermometers should be used in the Colorado River system). The thermometer should be allowed to equilibrate for at least 3 minutes prior to reading temperature. Care must be taken to read the thermometer while the bulb remains submerged.

Where possible horizontal temperature profiles (across stream) should be made at least once during each sampling period. A minimum of 3 and preferable 5 equally spaced temperatures should be measured across the river or stream, in a line perpendicular to the velocity vector of the stream. A minimum of elapsed time should be expended while making these measurements to insure that as close to a steady-state condition as possible exists during the cross-sectional profile measurement.

pH--pH is a measurement of the hydrogen ion activity or concentration in an aqueous solution. It is a logarithmic function which usually ranges from 1 to 14 units (acidic to alkaline, respectively). A pH of 7.00 represents a neutral solution. pH must be measured either *in situ* or rapidly after sample collection to minimize changes due to degassing of CO_2, precipitation (such as carbonates), or other chemical and physical reactions that cause the pH of the water sample to change.

The pH will be measured using an Orion Model SA 250 digital pH meter, with the appropriate combination electrode and automatic temperature compensation probe. The meter will be calibrated before **EACH** use with two buffers, pH 7.00 and pH 10.0 using the “autocalibration” mode. The following procedure is used to calibrate the pH meter:

1. Connect the electrode and ATC probe (if appropriate) to the appropriate connectors on the pH meter. Slide the mode switch to the pH 0.01 position. Check the saturated KCl level in the electrode and fill from supplied bottle, if necessary. Uncover filling solution hole in the electrode before measurements are made.
2. Rinse the electrode and probe thoroughly, and gently wipe dry with a tissue.
3. Transfer a small portion of pH 7.00 buffer to a clean cup and submerse electrode and probe stirring vigorously to dislodge bubbles.
4. Press the CAL button and observe the display alternating between 1 and approximately 7. Wait for a stable reading and press ENTER. The display will hold for about 3 seconds and then advance to 2, indicating that the meter is ready for the pH 10.00 buffer. Do not dispose of pH 7.00 buffer.
5. Rinse electrodes with deionized water and submerge in pH 10.00 buffer stirring to remove air bubbles. When stable pH is achieved press ENTER. After the second buffer has been entered, the letters pH will be displayed indicating the meter is ready for pH measurement.
6. Remove electrodes and rinse with deionized water. Dry electrodes with a tissue. Use a clean cup and transfer a small portion of the pH 4.01 buffer to a cup. Submerse electrodes with vigorous stirring to remove bubbles. Record pH value in the Field Notebook
7. Rinse electrode and probe with deionized water, dry and resubmerse in the pH 10.00 buffer. Record observed pH in the Field Notebook. Repeat same procedure with the pH 7.00 buffer.
8. Rinse and dry a final time and place in sample and measure pH.

NOTE - ALWAYS BE SURE METER READINGS HAVE STABILIZED BEFORE RECORDING FINAL pH READING.

All measured pH's should be recorded in the permanent record to the nearest 0.01 pH unit.

SPECIFIC CONDUCTANCE--Specific conductance is a measure of the total ionic strength of an aqueous solution. It is determined by the measurement of solution resistance, reference at 25° C. The determination is easily made in the field, and gives results that are useful for a general indication of the dissolved-solids concentration.

As with pH, specific conductance may change with time after sample collection, therefore, measurements should be made in situ, or as rapidly as possible after sample collection or compositing. When using the Model 515 dip cell, care must be used to insure that the cell is immersed to a depth of at least 5 cm above its bottom (the end opposite the cable connection). The cell should be rapidly moved in an up-and-down motion to dislodge any trapped air bubbles.

The calibration of the Model 604 Digital Conductivity Meter should be field checked by the following procedure:

1. Measure the provided specific conductance reference standard by submersing the cell to the proper depth in the standard solution and turn main power switch to the "on" position. Function switch should be placed to the "on 25 C" position and the range switch should be placed at "2000". At sites where the specific conductance is known to be high, appropriate adjustments to measuring procedures should be made to accommodate these types of samples.
2. After moving the cell up and down several times to dislodge air bubbles, read conductivity immediately after display stabilizes.
3. Record date, time and meter reading for the standard solution on the provided form.
4. Calibration standard should be checked before each sampling period.

Samples should be measured with the same meter settings as used in the calibration procedure. To prevent erroneous meter readings, care must be taken not to submerse the cell totally in water when readings are made. Each time a specific conductance measurement is made, water and air temperature should be recorded at the same location.

ALKALINITY--Alkalinity is the acid neutralizing capacity of an aqueous solution. Along with pH, it is the basis of measurement of carbonate and bicarbonate concentrations in natural waters. Carbon dioxide loss, precipitation and other chemical and physical reactions may cause the alkalinity of some waters to change dramatically within several hours or even minutes after sample collection. Consequently, field measurement of alkalinity is usually more reliable than when measured in the laboratory. If the pH of the sample is >8.3 then appreciable carbonate will be present, resulting in two endpoints for the Gran's titration curve.

All samples for alkalinity titration should be field filtered prior to titration. Filtration should be carried out using the supplied syringe filters attached to a 60 mL plastic syringe using the following procedure:

1. Remove the plunger from a clean syringe, attach a disk filter and fill to 55 mL with sample, avoiding contamination.
2. Expel sample through the filter until the syringe plunger is aligned with the 50 mL mark on the syringe barrel.
3. Expel exactly 50 mL of sample through the filter into the titration vessel (beaker).
4. Immediately rinse the syringe with deionized water and return the syringe to a plastic bag to prevent contamination.
5. If the filter plugs with suspended sediment, note the volume of sample transferred from the reading on the syringe barrel, refill the syringe as instructed in steps 1 and 2, expel additional sample into the titration vessel such that the total volume expelled equals exactly 50 mL.

Alkalinity on the filtered sample is determined by titration with a 0.16 N standard sulfuric acid solution to an end-point of pH 3.5. The following procedure must be used to perform the alkalinity titration and data recording:

1. Calibrate the pH meter according to the instructions under pH Section. Rinse electrodes thoroughly and dry lightly with a clean laboratory tissue.
2. Place electrode into 50 mL sample with stirring bar on magnetic stirrer and record initial pH.
3. Fill digital burette with 0.16 N H_2SO_4 or insert cartridge, where appropriate.

4. The delivery tube from the burette must be placed below the surface of the sample. Rotate the delivery knob of the burette so that a volume of acid is added to the sample.
5. After each increment of acid is added to the sample continue stirring for at least 30 seconds and then turn off stirring motor and read sample pH after the meter stabilizes.
6. Record both the volume increment of acid added and the pH after each addition. The pH of the sample will be extremely sensitive to small additions of acid, so great care must be used to insure accurate readings are obtained.
7. After reaching a pH of 5.5, add smaller increments of acid until reaching a pH of 4.5, this will usually be only 1 or 2 units on the digital pipette. (If starting pH is >8.3 then smaller increments will need to be added immediately continuing until reaching a pH of 7.5. Larger increments can then be added until reaching pH 5.5).
8. After completion of titration, thoroughly rinse all equipment with deionized water and store for next sampling period. Alkalinity, carbonate and bicarbonate values will be calculated from the titration data at a later time.

DISCHARGE--Use conventional stream discharge measurement procedures.

DISSOLVED OXYGEN--Oxygen dissolved in surface water is a combination of oxygen from the air (dissolved by diffusion) and oxygen produced from aquatic plants during the process of photosynthesis. The solubility of oxygen is dependent on the partial pressure of oxygen in the air, the temperature of the water, and the chemical composition of the water. The measurement of dissolved oxygen provides a great deal of insight to biological and chemical processes underway in a river or lake. The longitudinal extent of photosynthesis or respiration in a river can be estimated by measuring the *in situ* dissolved oxygen. With the use of a dissolved oxygen meter the task is simple. The meter probe is placed in flowing water in an area where the water surface is unbroken, and the dissolved oxygen measured and recorded.

Locate an area near the river bank that has a steady unbroken flow. Calibrate the dissolved oxygen meter and place the probe about 6-12 inches below the water surface and measure and record the dissolved oxygen. Measurements should be made at 1 hour intervals whenever possible. At times this can not be accomplished, as the meter will be used elsewhere, but whenever possible, make the measurements every hour. Record the data with date, military time, and note the light conditions, such as bright sunlight, cloudy, or dark. Also, qualitatively note the degree of darkness. This is important in the Grand Canyon, because of the influence of the steep canyon walls on light intensity.

Operate meter as follows:

1. Check “mechanical zero” on meter.
2. Turn meter on, allow at least 1 hour warm-up.
3. Check membrane for air bubbles and smoothness.
4. Dip calibration chamber in water and pour off excess.
5. Insert probe into wet chamber making sure no water leaks in and no droplets of water are on membrane.
6. Place in water and allow time for temperature of air in chamber to equilibrate.
7. Read barometric pressure and temperature in calibration chamber.
8. Determine the dissolved oxygen saturation value from Oxygen Solubility Table; apply a salinity correction if necessary. Record all information.
9. Check “redline” and zero; adjust if necessary.
10. Select scale and adjust calibration knob to DO value obtained from saturation table.
11. Remove probe from calibration chamber and place in water, making measurements in water velocities of at least 1 ft/sec.
12. Read and record value to nearest 0.1 mg/l.

SECCHI DISK--The measurement of light penetration through the water column provides insight to water clarity and depth of the euphotic zone. Under ideal circumstances a submarine photometer is used. This equipment is, however, expensive and delicate. We will use a photometer at several stations, including Lake Powell. At most river stations we will use a Secchi disk, which is simply a black and white disk that is lowered into the water and the depth at which it disappears is noted.

Locate a site where the water is slowly flowing, such as the site for the measurement of photosynthesis. Select as deep a site as possible, which often will mean working from the back of a boat, or from a vertical bank. Lower the Secchi disk into the water in a vertical manner until it disappears from sight. Then slowly raise the Secchi disk until it just reappears. Note and record the water depth in meters that the disk reappears to your sight; this is the Secchi disk reading.

PHOTOSYNTHESIS AND RESPIRATION--Photosynthesis (P) is the process whereby chlorophyll containing plants synthesize cellular material. Respiration (R) is the process whereby organisms break down cellular material to obtain energy. Photosynthesis occurs in the presence of light, whereas respiration occurs constantly in the light and in the dark. A useful measurement in determining processes in aquatic ecosystems is the "P/R ratio". Another useful measurement is that of primary production which can be measured by dissolved oxygen uptake and release during daylight hours. Primary production is simply gross and net photosynthesis and is measured either with the carbon-14 method, or more simply with the oxygen light-and-dark bottle method. The oxygen light-and-dark bottle method will be used during the Synoptic Studies on the Colorado River. This technique consists of using paired 300 mL biochemical oxygen demand (BOD) bottles filled with unfiltered river water. One bottle is left uncovered so that light may penetrate through the glass and trigger photosynthesis (light bottle). The other bottle (dark) is first covered with black electricians tape to prevent light passage, and then covered with aluminum foil to reflect heat. The initial dissolved oxygen (I_b) is determined for the bottles, and they are then suspend in the water. A general rule of thumb is to suspended two pairs of bottles (two light and two dark) every meter in depth from the surface to the bottom. After a period of incubation the bottles are retrieved, and the final dissolved oxygen (L_b and D_b) is determined.

Locate an area where the flow is minimal and at least one meter in depth. Obtain paired light and dark bottles. Fill a container having a capacity of 8-10 liters with water from the selected site, and let stand for 15-30 minutes. After this period determine the dissolved oxygen concentration which is the initial concentration and designated as I_b. Also record the water temperature. Carefully fill the light and dark bottles with water from the container being careful not to agitate and increase the dissolved oxygen concentration. Stopper the bottles insuring there are no bubbles or air space in the bottle. Immediately suspend the paired bottles, two pair (two light and two dark) per each meter of depth, starting just below the surface. Incubate the bottles for about 4 hours; (1000 to 1400 are generally the best hours). After incubation remove the bottles and immediately determine the dissolved oxygen in each bottle and record as D_b, or L_b. Construct a table as follows for the dissolved oxygen values:

Dissolved Oxygen **Temp._____**

Time in: Time out:

Depth	I_b	L_b	D_b
Surface	_____	_____	_____
1 meter	_____	_____	_____
2 meters	_____	_____	_____
do.	_____	_____	_____

Note that the I_b dissolved oxygen value will be the same for all bottles. The change in dissolved oxygen (absolute values) in the light bottle is net photosynthesis. The change in dissolved oxygen in the dark bottle is due to respiration. If we add the change in dissolved oxygen in the dark bottle to the change in dissolved oxygen in the light bottle the result is gross photosynthesis. It is extremely important to measure the dissolved oxygen carefully, and immediately upon on retrieval of the bottles. The amount of dissolved oxygen in the water is a function of pressure and temperature. The meter must be calibrated to pressure and the temperature of the water determined at each reading. If you must hold the bottles out of the water for a short time either in establishing them for suspension or upon retrieval, keep them cool and in the dark. There are several ways to suspend the 300 mL BOD bottles. The best method is to suspend them in a horizontal manner.

FIELD OBSERVATIONS--One of the most important pieces of information a researcher can have is accurate field notes of observations made during a period of intense study such as the Synoptic studies. Such notes fill important gaps in our knowledge, and help explain anomalies in the data and findings. They also provide important insight to the data. There is no easy way to tell you what to record, nor what to look for as a part of your field notes. The best rules of thumb are threefold: 1) Field notes are extremely important and thus deserve dedicated time to record. Do not rely upon your memory. One way to remember as well as to extend the time between writing is to carry a small dictating devise and speak into it from time to time. Then, when the opportunity arises, you can record your notes on paper; 2) Watch the river. What is moving downstream? Is there a concentration of foam? Any insect activity above the river surface? Any unusual flow regimes?; 3) Observe the sampling and sample processing procedures. Often flow conditions require modifications. Be certain that such modifications are recorded. Also, if someone makes a measurement error that cannot be repeated, note that in your field notes. All researchers look for anomalies and high and low values in the data. We must be certain that such values are real, and not a sampling artifact. We ask that you specifically note the occurrence of fronds of *Cladophera* moving past your sampling site, the occurrence and time extent of sediment-laden water (which can occur from storms in the tributary drainages or along the mainstem below Glen Canyon Dam), and the time of extreme high and extreme low water. At the extreme high and low water measurements it is important to record the dissolved oxygen and water temperature. Finally, we must have the weather at the site recorded every three hours. Note cloud cover, periods and extent of rainstorms, and air temperature.

CHEMICAL SAMPLE COLLECTION

DISCHARGE WEIGHTED SAMPLING PROCEDURE--Sampling at all sections will be by the Equal Discharge Increment (EDI) method using the D-77 (metals and organics) sampler, with a Teflon bag liner inside the plastic bottle, at both cable and boat sampled mainstem sections. The DH-81 sampler, with a Teflon bag liner is used at tributary sections. In all cases, as nearly as possible equal volumes of sample (1 - 1.5 liters each) will be collected from verticals at the mid-points of each of five equal discharge increments in the cross-section.

At each cableway section, a table is provided in the appendix which, for a range of discharges, lists the five positions along the cable at which to locate the sampling verticals. Before sampling, determine the discharge at the station by reading the staff gage and consulting the rating table for the gage. Next determine the correct position of the sampling vertical by interpolation in the table provided. At the boat-sampled mainstem stations, sampling verticals will be located at the centroids of equal-area increments. This will necessitate measurement of a cross-sectional depth profile before the 48-hour sampling period begins. Plot the cross-section and determine the five approximate centroids of volume. Attempt to hold the boat at these same sampling verticals (distances from the bank) during each of the sampling periods.

At wading sections, the five centroids of discharge will be determined from the discharge measurements made at the time of sampling. Transit rates should be held as constant as possible within each vertical to insure that a representative depth-integrated sample is obtained. Do not allow the sampler to sit on the river bottom before retrieval (move at a constant transit rate). It is not necessary that transit rates for each vertical be the same, however; once a transit rate is selected for each vertical, it must remain constant for the entire upward or downward transit.

COMPOSITING--Samples from each vertical will be collected in Teflon bags. Be careful to insure samples and sampling equipment are handled with polyethylene gloves. Transfer sample from each vertical to the graduated cylinder (sieving the sample through the provided nylon sieves) and measure the volume and record. Also record the Price Current Meter clicks and total time of the vertical transect for each vertical. After recording volume, transfer sample to the Teflon-coated stainless steel churn for compositing. When all five verticals are completed, about 7.5 liters of sample should be in the churn. Use standard churn splitting procedures, consulting the attached table for splitting procedures.

NOTE - "TAYLOR" DEIONIZED WATER MUST BE USED IN ALL SAMPLE PROCESSING PROCEDURES. OTHER DEIONIZED WATER MAY BE USED FOR TITRATIONS, ETC.

MAJOR CONSTITUENTS--The dissolved components of water samples can be classified according to their general indigenous concentration levels. Those constituents present at concentration levels generally greater than 1 mg/L comprise the bulk of ionic materials that contribute to the specific conductance and the dissolved solids. Accurate measurement of these materials are necessary to characterize the general water chemistry of the samples. Calcium, magnesium, sodium, and potassium are categorized as major constituent cations. Anions such as chloride, sulfate and silica (reported as SiO_2) are the corresponding counter ions. These coupled with hydrogen ion (determined from pH measurements) and carbonate/bicarbonate (determined from alkalinity titrations) represent the major water chemistry constituents. Even though these are dissolved materials and should be relatively homogeneously distributed in water samples, differences in surface and ground-water sources can result in rather significant concentration gradients of these materials in natural waters. Therefore, discharge weighted, depth and width-integrated sampling techniques are required to insure that statistically representative samples are obtained.

After sampling and compositing (see **CHEMICAL SAMPLE COLLECTION**), a 500 mL subsample for the major cations determination is split from the composite churn into a sample-rinsed Teflon bottle. This same subsample is used for trace metals processing, and the filtration process is described in that Section. A 250 mL subsample for major anion determination is split from the composite churn into a sample rinsed, black capped, polyethylene bottle which will not be preserved other than by chilling (keep sample on ice at approx. 4^o C.). Rinse bottle with about 20 mL of sample and discard (this is a **MUST** for all subsamples), before filling to top, try not to leave an air space in bottle.

NUTRIENTS--Nutrients represent an important group of constituents that are extremely important in controlling the biological productivity of the river system. They consist of elements that are necessary for the growth of plants and ultimately animals. In excess, some nutrients can create potentially noxious situations by promoting algal blooms and other conditions and cause nuisance conditions such as taste and odor.

Nutrients, as discussed here, consist of nitrogen containing species, ammonium, nitrate, nitrite and organic nitrogen; and phosphorus expressed as both orthophosphate and total phosphorus species. **ALL** nutrients will be determined as present in the **DISSOLVED** phase. Therefore, all samples for nutrients analysis must be field **FILTERED.**

After sampling and compositing (in churn), a subsample will be filtered through a 0.45 µm silver-membrane filter (the same filtering procedure and apparatus used for dissolved organic carbon), into 3 precleaned, opaque, 250 mL polyethylene brown bottles. Discard the first 20 mL of sample filtered. The appropriate labels are affixed to the bottles and the samples are immediately stored chilled in an ice chest. One bottle will be labeled for "Nutrients", the second bottle, "Total Nitrogen" for organic nitrogen and the third bottle, "Total Phosphorus" for total phosphorus species. After filtering, the silver filter must be carefully removed from the holder and stored chilled in a labeled petri-dish for suspended organic carbon determinations. If possible, all samples should be filtered through a single silver membrane filter; however, if the suspended sediment concentration is so high that the filter clogs quickly, the filter may be changed (Note - only 3 silver filters have been provided for each sample period). See DOC section for specific instructions on using the pressure filtration apparatus.

DISSOLVED ORGANIC CARBON--Dissolved organic carbon (DOC) is the organic carbon passing through a 0.45 µm silver membrane filter. This measurement quantifies the chemically reactive fraction and gives the mass of organic carbon dissolved in a water sample. It is a reliable measure of the many simple and complex organic molecules making up the dissolved organic load. The procedure for processing sample for DOC involves pressure filtering the sample through a 0.45 µm silver membrane filter housed in a stainless steel pressure filtration apparatus (Gelman Instrument Model 4280).

The procedure for filtration is as follows:

1. A silver filter is inserted into the lower section of the barrel filter using forceps (care must be used to avoiding damage to the filter. Note - do **NOT** use the same Teflon coated forceps that are used to handle the Nuclepore filters described below.) Make sure the gaskets are properly aligned and hand tighten the middle section of sampler onto the base with filter.
2. About 150 mL of sample is poured into the filter apparatus and the top section is hand-threaded onto the top of the barrel and the gas line is connected to the nitrogen cylinder.
3. The regulator is carefully adjusted to 25 pounds per square inch (higher pressures may rupture cell walls, invalidating DOC measurements).

4. Sample is filtered into a 125 mL brown glass bottle. The first 20 - 25 mL of filtered sample is used to rinse the bottle and cap, and is subsequently discarded.
5. Fill the bottle completely and cap tightly. Label and chill immediately.
6. If the filter is not clogged sufficiently to inhibit filtration, this same filter and apparatus can be used to filter nutrient samples (see Section on nutrients above).

TRACE ELEMENTS--Inorganic materials in the dissolved aqueous phase at concentration levels below 1 mg/L are classified as trace elements. These consist of cationic or anionic species that pass through a filtration process with a particle size cutoff of 0.4 micrometers (μm).

Often biologically toxic inorganic materials are present at trace concentration levels. In addition, a complete understanding of water chemistry processes requires a general knowledge of the trace elemental composition of the dissolved phase. The following trace elements will be determined in the aqueous phase: Al, As, B, Ba, Cd, Co, Cr, Cu, Fe, Hg, Li, Mn, Mo, Ni, Pb, Se, Tl and U. Additional information on the association of trace metals with specific size-fractions of suspended material will be determined on the residues retained on filters, and the special samples collected for field flow fractionation (FFF) measurements.

Two subsamples of the discharge weighted depth- and width-integrated composite (from churn) are collected in a sample rinsed 500 mL Teflon holding bottle and a 250 mL Teflon holding bottle. These samples are filtered through 0.4 μm Nuclepore filters housed in an all Teflon apparatus. The procedure for filtration is as follows:

1. Extreme care must be used during filtration and when handling filter apparatus to avoid contamination. At all times equipment must be stored in plastic bags to prevent dust contamination, and plastic gloves must be worn by the operator.
2. Set up filtration apparatus using filter holder and vacuum system.
3. Place membrane filter in apparatus using Teflon-coated tweezers. Be careful to orient filter in the holder so that the shiny side is up. Filters are packed with shiny side down, between paper spacers. Use care to avoid puncturing the filter with the tweezers. Grip the filter at the edge and avoid wrinkling filter when tightening filter holder.
4. Rinse filter with about 50 mL of 0.1 % HNO_3, the rinse solution is prepared by dosing 0.5 mL of concentrated high purity HNO_3 from Teflon dosing bottle (1 dose) into the 500 mL bottle that is provided marked **ACID RINSE** (use safety glasses). Fill bottle with deionized water, and shake to mix thoroughly. Vacuum filter to dryness, then rinse filter with about 100 mL of deionized water (rinse water is prepackaged in each of the RED capped bottles) (vacuum filter to dryness). Dispose of acid-rinse and water-rinse into waste bottle and discard into provided waste storage.
5. Vigorously shake sample in Teflon holding bottle and pour about 20 mL into filter funnel. Filter into 250 mL RED capped bottle. Remove bottle from the apparatus, screw on cap and shake vigorously and discard.
6. Pour additional sample into filter funnel and continue filtering until bottle is approximately 7/8ths full. Cap bottle tightly and label. This will be the first trace element/major cation sample.
7. After filtration is completed, carefully remove sediment loaded filter with Teflon-coated tweezers from the filter holder and place in labeled Petri dish.
8. Repeat the identical procedures outlined in steps 3-7 to prepare the replicate trace element/major cation sample and its corresponding filter.
9. Repeat steps 3 and 4 to prepare a third filter for the Hg determination sample. Deionized rinse water is contained in the brown glass bottle. Use a 10 mL portion from the Hg determination holding bottle to rinse a 125 mL **CLEAR** glass bottle with filtered sample (7/8 full). Discard sample rinse and fill this bottle with filtered sample. After filtration is complete, rinse a 125 mL **BROWN** glass bottle with 10 milliliters of filtered sample, shake and discard, and then continue filtering from the "Hg determination holding bottle" until this bottle is 7/ 8 full.

10. If any of the filters are clogged sufficiently where the filtration process is slowed to the point of inhibiting further sample processing, use a new filter and go back to item 4, and rinse the new filter with 0.1 % HNO_3, deionized H_2O and sample.

11. After filtration is completed, carefully remove sediment loaded filter with Teflon-coated tweezers from the filter holder and place in labeled Petri dish. If extra filters were used in any of the steps, place them with the Hg filter in a third petri dish for later disposal. When completed there should be three Petri dishes with filters, one for each trace element sample and a third for disposal (includes Hg filter).

12. Both of the trace element/major cation sample bottles should be acidified with concentrated HNO_3, using the Teflon calibrated dosing bottle (be sure to wear safety glasses). Use **TWO** (2) doses of acid from the dosing bottle for each sample bottle. This represents a total of 1 mL of concentrated HNO_3 per 250 mL of sample (each dose from the HNO_3. dosing bottle is 1/2 mL). Tighten lids on bottles and shake to homogenize acid.

13. The **CLEAR** 125 mL Hg determination sample **ONLY** should be preserved with $K_2Cr_2O_4$-HNO_3 preservative. The brown 125 mL Hg determination sample is chilled.

14. When completed, there should be two RED capped sample bottles for trace element/major cations, one **CLEAR** glass Hg determination sample bottle and one **BROWN** glass Hg determination sample bottle, each appropriately labeled .

15. Each of the Petri dishes holding the filters from the filtration procedures should be identified and labeled with time, date, bar code numbers of samples processed through the filter and any comments in a corresponding fashion to the sample collected.

16. When all filtration is completed, thoroughly rinse all apparatus with deionized water and place in the appropriate plastic bags for storage.

17. Specific details of the entire procedure and the samples generated should be carefully recorded in the field notebook. Do not assume that information will be obvious, record **ALL** pertinent data.

BLANKS--Once per day, process a single portion of deionized water (as if it were a sample) through all sample handling procedures. This will generate a total of two blank samples for trace elements, nutrients, DOC, etc.

FIELD FLOW FRACTIONATION SAMPLE--A sample is collected for the study of colloidal size-fraction particles and their associated composition. These samples will be subsampled from the composited sample (from churn) directly into one of the small (60 mL) polyethylene screw capped bottles. Be sure and label the bottle immediately after filling and chill immediately.

SEDIMENT SIZE DISTRIBUTION AND CONCENTRATION--A sample is collected for the measurement of the size distribution and concentration of suspended matter (<63 mm). These samples are subsampled from the composited sample (from churn) into one of the 1 liter bottles. Use chloroform to preserve the samples, if available (10 mL per sample bottle). If it is not available, keep unpreserved sample chilled until transport to the laboratory. The bottle is tightly capped and labeled.

BIOLOGICAL SAMPLE COLLECTION

DRIFT--The term "drift" refers to material and organisms moving with the current. In many instances it is living benthic invertebrates, but also consists of parts of plants and animals. Most often we measure the near-surface drift, which consists mostly of organic material rather than bedload or other denser-than-water particles. The most common way to measure drift is to place nets having a given orifice and mesh size into the current of the stream for a given time period. In our case we place the nets near the shoreline (because of the water depth of the river) using reinforcement bar (rebar) driven into the river bottom to hold the nets. The nets we use have an orifice opening of 100 mm (4-inches) and a mesh having pore openings of 250 micrometers (μm). The top of the net orifice is maintained just below the surface of the water. Since the river stage rises and falls rapidly and on an irregular basis, the nets may need to be moved several times to keep them at the surface of the water. After being in the river for one hour the nets are removed and the contents placed into containers and preserved. Note - In order to quantify the drift it is necessary to know the velocity of the water entering the net in feet per second (fps). Thus, before the net or rebar are removed, this measurement must be made. Also, once the nets are in place there should be no upstream disturbance. The nets should only capture natural drift, not that caused by sampling or other upstream activity.

Locate a somewhat shallow area (<2 feet in depth) where the water is visibly moving downstream. Drive two rebar stakes about 4 inches apart into the river bottom until they are steady. Repeat the procedure at another similar site. Place the nets between the rebar with the top of the net just above the water line. Secure the nets with an elastic cord, by squeezing the rebar rods together against the opening of the net. Be certain that the safety cord of the net is looped over one of the rebar stakes to prevent loss of the net should it slip from between the two rebar rods. Note and record the time the net is set, using military time. Because of fluctuating river levels it may be necessary to raise or lower the nets on the two rebar stakes during the set period. After one hour, remove the nets from the river, and wash the contents into the plastic container attached to the end of the net. Remove the drift contents from the plastic container by unscrewing the lid, and place into a sample jar. Consolidate the contents of all nets into a single jar if possible. If not possible, use another jar and mark it "2 of 2" on the label. The velocity in feet per second must be measured and recorded on the label for each net. Preserve with a 50 % mixture of water and ethyl alcohol. Label the contents with the following information: 1) drift, 2) location of station, 3) time nets were set, 4) feet per second in front of nets and 5) date. Place the label **INSIDE** the sample bottle, and close the lid tightly. Finally, seal the lid to the bottle with a wrap or two of electrician's tape.

BIOLOGICAL PIGMENTS--The most useful biological pigment for determining phytoplankton biomass is Chlorophyll-α. This pigment is found in all oxygen-producing algae, both phytoplankton and periphyton. The major problem in collecting Chlorophyll-α in remote field areas such as the Grand Canyon is that the sample must be frozen immediately after collection. Thus we must by necessity limit the collection of Chlorophyll-α samples to specific sampling stations during our synoptic studies. The method consists of passing a known amount of water through a glass filter, rolling the filter with its contents inside, placing the rolled filter and contents into a darkened bottle or vial, and freezing until laboratory analysis with a spectrophotometer. Collect a water sample using a depth-integrated sampler, or a water bottle (sample may be removed from a churn splitter.) Place a glass 47-mm diameter filter onto a filter funnel and vacuum or pressure filter a known amount of water through the filter. Use no more than 25 psi with the pressure apparatus. Observe and record the amount of water passing through the filter. Remove the filter and roll tightly with the contents inside. Place in a darkened bottle or vial and immediately freeze. Keep frozen until analysis. The amount of water to pass through the filter is empirical, and must be determined for each sampling circumstance. Often the filter clogs when there is still water in the funnel. If this happens, note the amount of water that passed through the filter. Next, discard this water, save the filter, and the water in the funnel above the filter. With a new filter in place, add the saved water to the funnel and again filter. Another technique is to add water to the funnel in small amounts until the filter clogs. The goal is to filter as much water as possible, but under ideal circumstances a liter is sufficient.

BENTHIC INVERTEBRATES FROM STREAM BOTTOM--The benthic invertebrate community in the Colorado River is small and in some instances may be absent. The purpose of this sampling procedure is too obtain insight to their location, and the types that might be present. We do this with a “kick net”, which is a qualitative sampler. The net is held in the stream by its brailles, and a person immediately upstream from the net dislodges the stream bottom material. This material with its associated organisms are washed into the net. The net is removed from the water and the organisms placed in a bottle containing 50 % mixture of alcohol and water. Benthic organisms are most often the immature stages of aquatic insects. They must be in the water at all times, for they breathe through gills. Thus, they will not be found on the stream bottom between the high and low water areas of the river. If they are found at all, they will be on the stream bottom, especially riffle areas, that are present (wet) during low flows. Thus, sample for them **ONLY** during the lowest flow time of each day. This may be at night.

At low flow, select a riffle area less than a meter in depth. Have one person hold the net brailles, insuring that the bottom edge of the net is firm against the stream bottom. The second person disrupts the stream bottom in front of the net. Standard practice is to disrupt approximately a square meter of stream bottom. When completed raise the net upward and in an upstream direction. Be careful not to lose the contents. Place the net on a flat surface and remove the organisms with a pair of forceps. Place the organisms in a bottle containing a 50 % mixture of alcohol and water. Label the bottle, noting the date, time, depth of water, location of sampling site, size and type of stream bottom material, and approximate size of stream bottom area disturbed. Place the label inside of the bottle. Seal the bottle to the lid with electricians tape.

DISCHARGE AND SAMPLING TABLES FOR CABLEWAYS
